BAYESIAN CRAMER-RAO BOUNDS FOR FACTORIZED MODEL BASED
LOW RANK MATRIX RECONSTRUCTION

ABSTRACT

Low-rank matrix reconstruction (LRMR) problem considers estimation (or reconstruction) of an underlying low-rank matrix from under-sampled linear measurements. A low-rank matrix can be represented using a factorized model. In this article, we derive Bayesian Cramér-Rao bounds for LRMR where a factorized model is used. We first show a general informative bound, and then derive several Bayesian Cramér-Rao bounds for LRMR where the sensing operator $A$ has a special structure.

There exists several reconstruction algorithms for LRMR [3–9,11]. A natural question is how to benchmark the performance of algorithms against theoretical bounds. In this paper, we address the question for Bayesian algorithms where the low-rank matrix is modeled as the product

$$X = LR^T,$$

where $L \in \mathbb{R}^{p \times r}$, $R \in \mathbb{R}^{q \times r}$ and $r < \min(p,q)$ is a user-defined constant. Note that $\text{rank}(X) \leq r$. We refer to the model (2) as the factorized low-rank matrix model. The model is the basis for several algorithms, e.g. [3,5–9,11]. Our contribution in this article is to derive Bayesian Cramér-Rao bounds (BCRB) for LRMR problem that uses the factorized model (2). Then through numerical simulations, we compare the performance of practical Bayesian LRMR algorithms against the derived BCRB bounds. At this point we mention that there exists bounds for the deterministic scenario of LRMR, such as Cramér-Rao bounds for unstructured [9,11] and structured [3] low-rank matrices. In the following subsections, we explain notations used in the article and provide preliminaries of BCRB.

1. INTRODUCTION

In low-rank matrix reconstruction (LRMR) problem, a low-rank matrix $X \in \mathbb{R}^{p \times q}$ is measured as

$$y = A(X) + n$$

where $y \in \mathbb{R}^m$ is measurements, $n \in \mathbb{R}^m$ is $N(0, \beta^{-1}I_m)$ measurement noise with precision $\beta > 0$ and the linear sensing operator $A : \mathbb{R}^{p \times q} \rightarrow \mathbb{R}^m$ can be expressed as

$$A(X) = \begin{bmatrix}
\text{tr}(A_1^T X) \\
\text{tr}(A_2^T X) \\
\vdots \\
\text{tr}(A_m^T X)
\end{bmatrix} = A \text{vec}(X),$$

where $\text{vec}(\cdot)$ is a standard vectorization operator and the matrix $A \in \mathbb{R}^{m \times pq}$ is an equivalent representations of the sensing process. The problem is to reconstruct $X$ from the measurements $y$. LRMR has applications in e.g. system identification [1–3] and recommendation systems [1,4–10]. In several applications, the LRMR problem setup (1) is under-determined, i.e. $m < pq$. Here we mention that problem of low-rank matrix completion is an important special case of LRMR where the sensing operator $A$ has a special structure.

1.1. Notations

We use $E_q[\cdot]$ to denote the expectation value of a random variable with respect to variables $q$ and use the symbol $\otimes$ for the Kronecker product. The $\ell_2$-norm and Frobenius norm are denoted by $\|\cdot\|$ and the $k \times k$ identity matrix by $I_k$. We denote the $(i,j)^{\text{th}}$ component of a matrix $X$ by $[X]_{ij}$ and the $i^{\text{th}}$ standard unit vector by $e_i$, that is $[e_i]_j = 1$ if $j = i$ and zero otherwise. The commutation matrix $K_{pq} \in \mathbb{R}^{pq \times pq}$ is the matrix representation of the transpose operation, i.e. $K_{pq} \text{vec}(Z) = \text{vec}(Z^\top)$ for all $Z \in \mathbb{R}^{p \times q}$. We also introduce the linear operators $T_1$ and $T_2$ which operate on Kronecker products as $T_1(C \otimes D) = (C^\top \otimes D)$ and $T_2(C \otimes D) = (C \otimes D^\top)$ where $C \in \mathbb{R}^{p \times q}$ and $D \in \mathbb{R}^{p \times r}$. 

...
For ease of notation, we often set $x \triangleq \text{vec}(X)$. Henceforth we use the variables $x$ and $X$ interchangeably and their explicit use will be clear from the context.

## 1.2. The factorized model

The factorized model promotes low rank by incurring column-wise block-sparsity in $L$ and $R$. For achieving column-wise block-sparsity, a convenient approach is to use the following priors [6–8]

$$ p(L|\gamma) = \frac{\Gamma(|\gamma|/2)}{(2\pi)^{p/2}} \exp\left(-\frac{1}{2} \text{tr}(L\Gamma L^\top)\right), $$

$$ p(R|\gamma) = \frac{\Gamma(|\gamma|/2)}{(2\pi)^{q/2}} \exp\left(-\frac{1}{2} \text{tr}(R\Gamma R^\top)\right), $$

where $\gamma = [\gamma_1, \gamma_2, \ldots, \gamma_r]^\top$ and $\Gamma = \text{diag}(\gamma)$. Here $\gamma_i$ is the precision of $i$th column vector of $L$ and $R$. The precisions $\gamma$ and $\beta$ are typically assigned Gamma distributions

$$ p(\gamma_i) = \text{Gamma}(\gamma_i|a + 1, b) = \frac{b^{a+\gamma_i} e^{-b\gamma_i}}{\Gamma(1+a)}, $$

$$ p(\beta) = \text{Gamma}(\beta|c + 1, d) = \frac{d^{c+\beta} e^{-d\beta}}{\Gamma(1+c)}, $$

where $\Gamma(\cdot)$ denotes the Gamma function, when they are random. For ease of notation, we denote

$$ w \triangleq \begin{bmatrix} \text{vec}(L) \\ \text{vec}(R) \end{bmatrix}. $$

The joint distribution of all variables is

$$ p(y, w, \gamma, \beta) = p(y|w, \beta)p(w|\gamma)p(\gamma)p(\beta). $$

The individual factor matrices $L$ and $R$ are not identifiable since $(LQ^{-1})(RQ^{-1})^\top = LR^\top$ for any invertible matrix $Q \in \mathbb{R}^{r\times r}$. The precisions $\{\gamma_i\}$ are also not identifiable since we can interchange without changing the model. We can therefore only estimate e.g.

$$ \eta = g(z) = \begin{bmatrix} \text{vec}(LR^\top) \\ s(\gamma) \\ \beta \end{bmatrix}, $$

where $z = [w, \theta, \beta]$ and $s(\gamma)$ is a symmetric function of $\gamma$.

### 1.3. The Bayesian Cramér-Rao bound

The Bayesian Cramér-Rao bound (BCRB), also known as the van-Trees inequality [12, 13] and the Borovkov-Sakhanenko inequality [13,14], provides a lower bound on the variance of unbiased estimators. To derive the BCRB, we need to compute the Fisher information matrix $F$ of $z$, given by

$$ F = J_y + J_w + J_\theta + J_\beta, $$

where the components of the individual terms are

$$ [J_y]_{ij} = \mathcal{E}_\gamma \frac{\partial \log p(y|w, \beta)}{\partial \gamma_i} \frac{\partial \log p(y|w, \beta)}{\partial \gamma_j}, $$

$$ [J_w]_{ij} = \frac{\partial \log p(w|\theta)}{\partial z_i} \frac{\partial \log p(w|\theta)}{\partial z_j}, $$

$$ [J_\theta]_{ij} = \frac{\partial \log p(\theta)}{\partial g} \frac{\partial \log p(\theta)}{\partial g}, $$

$$ [J_\beta]_{ij} = \frac{\partial \log p(\beta)}{\partial z_i} \frac{\partial \log p(\beta)}{\partial z_j}. $$

Here $z_i$ is the $i$th element of $z$. We denote the covariance matrix of the estimation error $\epsilon \triangleq \hat{\eta} - \eta$ as

$$ C_\epsilon \triangleq \mathcal{E}_{\epsilon, \epsilon^\top} = \mathcal{E}_{\epsilon, \epsilon} \left[(\hat{\eta} - \eta)(\hat{\eta} - \eta)^\top\right]. $$

**Proposition 1.** For any unbiased estimator $\hat{\eta}$, the covariance $C_\epsilon$ of estimation error $\epsilon$ is bounded as

$$ C_\epsilon \succeq \mathcal{E}_\epsilon \left[\frac{\partial g}{\partial z} \frac{\partial g}{\partial z}^\top\right] \left(\mathcal{E}_\epsilon \left[\frac{\partial g}{\partial z} \frac{\partial g}{\partial z}^\top\right]\right)^{-1} \mathcal{E}_\epsilon \left[\frac{\partial g}{\partial z} \frac{\partial g}{\partial z}^\top\right]. $$

It also holds that

$$ C_\epsilon \succeq \mathcal{E}_\epsilon \left[\frac{\partial g}{\partial z} \frac{\partial g}{\partial z}^\top\right] \left(\mathcal{E}_\epsilon \left[\frac{\partial g}{\partial z} \frac{\partial g}{\partial z}^\top\right]\right)^{-1} \mathcal{E}_\epsilon \left[\frac{\partial g}{\partial z} \frac{\partial g}{\partial z}^\top\right]. $$

Proof of Proposition 1 will be shown later in an extended manuscript. We obtain a lower bound on MSE by taking the trace of the inequalities. At this point, we mention that (7) is a much exercised BCRB [13], but this can be non-informative, for example if $\mathcal{E}_\epsilon \left[\frac{\partial g}{\partial z}\right] = 0$. Therefore we derived (8) as a relevant informative BCRB. Table 1 shows a nomenclature of various BCRB of associated variables.

### 2. BCRB FOR THE FACTORIZED MODEL

The following proposition gives the Fisher information matrix of the factorized model.
Proposition 2 (Fisher information matrix). For the factorized model, the Fisher information matrix is given by

\[
F = \begin{bmatrix}
F_w & 0 & 0 \\
0 & F_\gamma & 0 \\
0 & 0 & F_\beta
\end{bmatrix},
\]

(9)

where \(F_w\) is shown in (10), \(F_\gamma = \frac{p+q+2a}{2} \Gamma^{-1}\), and \(F_\beta = \frac{m+2c}{2\beta^2}\).

Deterministic \(\gamma\) and \(\beta\) correspond to \(a = c = 0\).

Proof of Proposition 2 will be shown later in an extended manuscript. Next, we evaluate

\[
\frac{\partial g}{\partial z} = \begin{bmatrix}
([R \otimes I_p], [I_q \otimes L])K_{r,q} & 0 & 0 \\
0 & \nabla_\gamma s & 0 \\
0 & 0 & 1
\end{bmatrix},
\]

(11)

where we used (6) and the following algebraic relation

\[\text{vec}(LR^T) = (R \otimes I_p)\text{vec}(L) = (I_q \otimes L)K_{r,q}\text{vec}(R).\]

Noting that \(\mathcal{E}_w[(R \otimes I_p), (I_q \otimes L)K_{r,q}] = 0\) as \(L\) and \(R\) are zero-mean, we find that the BCRB (7) is non-informative. We therefore compute the BCRB (8). We first evaluate

\[
\frac{\partial g}{\partial z} \frac{\partial g^\top}{\partial z} = \begin{bmatrix}
(RR^T \otimes I_p) + (I_q \otimes LL^T) & 0 & 0 \\
0 & \nabla_\gamma s & 0 \\
0 & 0 & 1
\end{bmatrix},
\]

where we used (11) and the standard relation \(K_{r,q}K_{r,q}^\top = I_{r,q}\).

We find that

\[
\mathcal{E}_w \left[ \frac{\partial g}{\partial z} \frac{\partial g^\top}{\partial z} \right] = \begin{bmatrix}
2 \sum_{i=1}^r \gamma_i^{-1} I_{pq} & 0 & 0 \\
0 & \mathcal{E}_x[\nabla_\gamma s][\nabla_\gamma s]^\top & 0 \\
0 & 0 & 1
\end{bmatrix},
\]

(12)

where we used that \(\mathcal{E}_w[(RR^T \otimes I_p) + (I_q \otimes LL^T)] = 2 \sum_{i=1}^r \gamma_i^{-1} I_{pq}\). Using (9) and (11) we find that

\[
\frac{\partial F}{\partial z} \frac{\partial F^\top}{\partial z} = \begin{bmatrix}
G_w & 0 & 0 \\
0 & G_\gamma & 0 \\
0 & 0 & G_\beta
\end{bmatrix},
\]

(13)

where

\[
G_w = \beta(RR^T \otimes I_p)A^\top A(RR^T \otimes I_p) \\
+ \beta(I_q \otimes LL^T)A^\top A(I_q \otimes LL^T) \\
+ \beta(RR^T \otimes I_p)A^\top A(I_q \otimes LL^T) \\
+ \beta(I_q \otimes LL^T)A^\top A(RR^T \otimes I_p),
\]

\[
G_\gamma = (\nabla_\gamma s)F_\gamma(\nabla_\gamma s)^\top = \frac{p+q}{2} (\nabla_\gamma s)^\top \Gamma^{-2} (\nabla_\gamma s)^\top,
\]

\[
G_\beta = F_\beta = \frac{m+2c}{2\beta^2},
\]

2.1. BCRB-I and II

We compute the BCRB (8) by taking expectation values with respect to \(w\). We state the bound in the following proposition.

Proposition 3. The BCRB-II of the factorized model is given by

\[
C_e \geq \begin{bmatrix}
(2 \sum_{i=1}^r \gamma_i^{-1})^2 (\mathcal{E}_w[G_w])^{-1} & 0 & 0 \\
0 & G_\gamma^{-1} & 0 \\
0 & 0 & G_\beta^{-1}
\end{bmatrix},
\]

where \(G_\gamma\) and \(G_\beta\) are given in (14) and

\[
\mathcal{E}_w[G_w] = 2\beta \left( \sum_{n=1}^r \gamma_n^{-2} \right) A^\top A + 2rI_{pq} \\
+ \beta \left( \sum_{n=1}^r \gamma_n^{-2} \right) \left( T_1(A^\top A) + T_2(A^\top A) \right) \\
+ \beta \left( \sum_{n=1}^r \gamma_n^{-2} \right) \left( \sum_{m=1}^q (I_q \otimes e_m)(e_m \otimes I_p)A^\top A(e_m \otimes I_p) \right) \\
+ \beta \left( \sum_{n=1}^r \gamma_n^{-2} \right) \left( \sum_{m=1}^q (I_q \otimes e_m)A^\top A(I_q \otimes e_m) \otimes I_p \right).
\]

The linear operators \(T_1\) and \(T_2\) are defined in Section 1.1. Since (12) and (13) are block diagonal, the BCRB-I of \(x\) is

\[
\mathcal{E}_{x,w} \left[ (\hat{x} - x)(\hat{x} - x)^\top \right] \geq \left( 2 \sum_{i=1}^r \gamma_i^{-1} \right)^2 (\mathcal{E}_w[G_w])^{-1}.
\]

Proof of the above proposition will be shown later in an extended manuscript.

2.2. BCRB-III

Computation of BCRB-III requires computing the expectation with respect to \(y\) and \(z = [w^\top, \gamma^\top, \beta^\top]^\top\). We state the bound in the following proposition.

Proposition 4. Assume that \(a > 1\) in (4) and \(c > 1\) in (5). The BCRB-III of the factorized model is given by

\[
C_e \geq \begin{bmatrix}
\left( \frac{2rb}{a} \right)^2 (\mathcal{E}_x[G_w])^{-1} & 0 & 0 \\
0 & (\mathcal{E}_x[G_\gamma])^{-1} & 0 \\
0 & 0 & (\mathcal{E}_x[G_\beta])^{-1}
\end{bmatrix},
\]

where now

\[
\mathcal{E}_x[G_w] = 2 - \frac{e}{d} \left( \frac{r^2b^2}{a^2} + \frac{r^2b^2}{a^2(a-1)} \right) A^\top A + 2rI_{pq} \\
+ \frac{1+c}{d} \left( r^2b^2 \right)^2 \left( T_1(A^\top A) + T_2(A^\top A) \right) \\
+ \frac{1+c}{d} \left( r^2b^2 \right)^2 \left( \sum_{m=1}^q (e_m \otimes I_p)A^\top A(e_m \otimes I_p) \right) \\
+ \frac{1+c}{d} \left( r^2b^2 \right)^2 \left( \sum_{m=1}^q (I_q \otimes e_m)A^\top A(I_q \otimes e_m) \otimes I_p \right),
\]

\[
\mathcal{E}_x[G_\gamma] = \frac{p+q+2a}{2} \mathcal{E}_y \left[ \nabla_\gamma s \right] \Gamma^{-2} (\nabla_\gamma s)^\top,
\]

\[
\mathcal{E}_x[G_\beta] = \frac{m+2c}{2\beta^2} - \frac{e}{d} \left( \frac{m+2c}{2\beta^2} \right)^2.
\]
\[
F_w = \begin{bmatrix}
\beta (R^\top \otimes I_p) A^\top A (R \otimes I_p) + (\Gamma \otimes I_p) \\
\beta (R^\top \otimes I_p) A^\top A (I_q \otimes L) K_{r,q} \\
\beta K_{q,r} (I_q \otimes L^\top) A^\top A (R \otimes I_p)
\end{bmatrix}.
\]

**Proof.** The bound BCRB-III can be computed from BCRB-II by taking the appropriate expectation values with respect to \( \gamma \) and \( \beta \). We find that

\[
E_\beta[\beta] = \frac{\alpha^2}{4}, \quad E_\beta[\beta^{-2}] = \frac{\alpha^2}{4(c-1)},
\]

\[
E_\gamma \left[ \sum_{i=1}^r \gamma_i^{-1} \right] = \frac{rb}{a}, \quad E_\gamma \left[ \sum_{i=1}^r \gamma_i^{-2} \right] = \frac{rb^2}{a(a-1)},
\]

\[
E_\gamma \left[ \left( \sum_{i=1}^r \gamma_i^{-1} \right)^2 \right] = \frac{rb^2}{a^2} + \frac{rb^2}{a(a-1)},
\]

where we assume that all expectation values are finite. With these expectation values we obtain the BCRB-III. \( \square \)

### 3. NUMERICAL EVALUATION

In this section we numerically evaluate the BCRB bounds and compare them to the performance of two low-rank matrix estimation methods - (1) variational Bayesian (VB) estimator of [8] and - (2) nuclear norm (NN) minimization based estimator (convex optimization based) [1]. The VB estimator uses the factorized model while NN is a convex optimization based estimator that does not use the factorized model. We provide the performance of NN estimator due to its widespread use. For simulations we only considered matrix completion where the sensing matrix \( A \) has one component in each row set to one and all other components zero, with the constraint that \( A \) has full row-rank. We measure the performance in terms of normalized mean square error

\[
\text{NMSE} = \frac{E_x[|X - \hat{X}|^2]}{E_x[|X|^2]}
\]

which we evaluate empirically for different values of the model parameters and averaged out for many realizations. In the simulations we fixed the signal-to-noise-ratio

\[
\text{SNR} = \frac{E_x[|A(LR^\top)|^2]}{E_x[|\mathbf{n}|^2]} = \frac{rb^2}{a(a-1)d}.
\]

In the simulations we first fixed the parameters values of \( \{p, q, r, m, a, b, c, \text{SNR} \} \) and then randomly generated the measurements matrix \( A \). We then drew the precisions \( \gamma \) from the Gamma distribution (4), the noise precision \( \beta \) from the Gamma distribution (5). Then the factor matrices were drawn from the distributions (3) and the measurements from (1).

### 3.1. Numerical rank

We find that the random matrix \( X = LR^\top \) has rank \( r \) with probability one. However, the effective rank is smaller when some precisions are large. Here we introduce the concept of a **numerical rank** that serves as a lower bound on the actual rank as

\[
nrank(X) \triangleq \frac{|X|^2}{|X|^2_{F}} \leq \text{rank}(X).
\]

Since the parameter \( b \) in (4) affects the magnitude of \( X \), only the parameter \( a \) affects the numerical rank. To investigate how the numerical rank varies with \( a \), we empirically evaluate the mean numerical rank \( E_{w,\gamma}[\text{nrank}(X)] \). The results for \( p = q = 100, r = 20 \) and \( b = 1 \) are shown in Figure 1.

We find that the mean numerical rank is about 18 for \( a > 100 \) and about 5.3 for \( a < 0.03 \). However, the variance is large for smaller values of \( a \) and BCRB-III does not exists for \( a \leq 1 \). Small values of \( a \) thus correspond to low numerical rank. The model thus generates approximately low-rank matrices even when \( r \) is comparatively high.

### 3.2. Performance of practical algorithms and BCRB

In the second experiment we evaluated BCRB-II and BCRB-III for \( X \) for matrix completion by setting \( a = c = 1 + 10^{-3}, b = 1, p = q = 10, r = 5 \) and SNR = 20 dB. We generated 25 measurement matrices, 25 values of \( \gamma \) and \( \beta \) and 10 matrices \( X \) and measurements \( y \) for each value of \( m \). The results are shown in Figure 2 where the NMSE is plotted against the sub-sampling factor \( \frac{m_n}{m} \). Note that NN estimator provides better performance than VB. The main reason is that NN estimator knows the noise parameter exclusively, whereas VB
infers all necessary parameters including noise parameter using a variational Bayes learning technique. For the choice of parameters, it turns out that the BCRB-II is consistently lower than the BCRB-III. However, the VB algorithm has a large gap in performance from both bounds and hence the problem of Bayesian algorithm design for matrix completion remains valuable. We also measured the numerical rank of the realizations of $X$. The distribution of numerical rank is shown in Figure 3. We see that the numerical rank is consistently lower than the actual rank $r = 5$.

4. CONCLUSION

In this article we computed Bayesian Cramér-Rao bounds for matrix reconstruction from linear measurements. For the factorized model, we found that while the standard BCRB (7) is non-informative, the BCRB (8) provides an informative lower bound. By evaluating the numerical rank we found that the model promotes low numerical rank when $a < 1$. However, the bound BCRB-III only exists for $a > 1$. We found that both the nuclear norm estimator and the variational Bayes estimator showed a considerable gap from the BCRB bounds. This shows that there still exists room for improvement of Bayesian low-rank matrix reconstruction algorithms.
